Diamond-like carbon (DLC) films were deposited on tungsten (W) tips under the KrF excimer laser in a laser chemical vapor deposition (LCVD) chamber. Raman spectroscopy showed that the deposited DLC films were phase-graded along the tips from the apexes. The DLC films were more diamondlike at or near the tip apexes. From numerical simulation, there is a strongly confined and enhanced optical field at the tip apexes. The simulation also indicates that there is an optical-field gradient from tip apexes to tip bodies. Therefore, the variations in the phases of deposited DLC films were attributed to the corresponding variations in local optical intensities along the tips. Hence, optical local near field was confirmed to be responsible to the DLC deposition. © 2005 American Institute of Physics. [DOI: 10.1063/1.1887840]

Recently, optical near-field enhancement has been intensively studied due to its important applications in near-field optics and near-field nanostructuring. By irradiation of metallic spheres or sharp metal tips with lasers, strongly confined and enhanced fields can be obtained at or near the metallic spheres and tip apexes. The enhanced near-field becomes an energy source with extremely high spatial resolution and highly enhanced power intensity. Applications exploiting such advantages include scanning near-field optical microscope (SNOM)^{1,2} and nanostructuring by laser-assisted scanning probe microscopy (SPM).³ However, use of optical near-field as the source for chemical vapor deposition (CVD) has not yet been investigated.

In traditional laser-assisted chemical reactions, such as laser-assisted deposition, etching and oxidation, lasers are used as an energy source responsible for photothermal as well as photolytic reactions. However, the spatial resolution is limited by the wavelength of the incident laser. Optical-near-field-induced deposition (ONFID) has potentials for highly localized deposition of materials on specific structures, e.g. sharp tip, sharp edges, nanometer-sized particles, which are capable of generating locally-enhanced optical fields under proper laser irradiation. Since wavelength and temporal characteristics of the enhanced optical near field are the same as those of the incident laser,⁴ any established laser chemical reactions can also take place under the optical near field. One of the potential applications of ONFID technique is to deposit protective diamond and DLC films on sharp tips or gears in MEMS or NEMS devices for abrasive applications. Due to the local field enhancement, relatively low incident laser fluence is required for localized coating at tips and sharp edges. Therefore, the deposition is in a cold-ambient process, in which other parts can remain intact.

Our previous study⁵ demonstrated that tip sharpness directly affected the morphology and phase of the deposited DLC film on W tips immersed in a precursor solution at similar laser process conditions. Near-field effects were suggested to play important roles in the deposition process due to that the degree of field enhancement varied significantly for tips with different sharpness. However, direct evidence of near-field induced deposition was not obtained. In this study, we conducted laser deposition of DLC on a W tip in a LCVD system. Raman spectroscopy showed localized and phase-graded deposition of DLC films on a single tip, which helped to confirm that optical near-field effects played a dominant role in DLC deposition on sharp nanotips.

W tips were homemade using dc electrochemical etching of W wires (0.25 mm in diameter).⁶ In this study, laser-assisted deposition was conducted in a laser chemical vapor deposition (LCVD) chamber. The experimental setup was shown in Fig. 1. A W tip was vertically attached to a sample holder. The chamber was first pumped to a base pressure of 1×10^{-7} Torr and a steady benzene vapor around 3.6 Torr

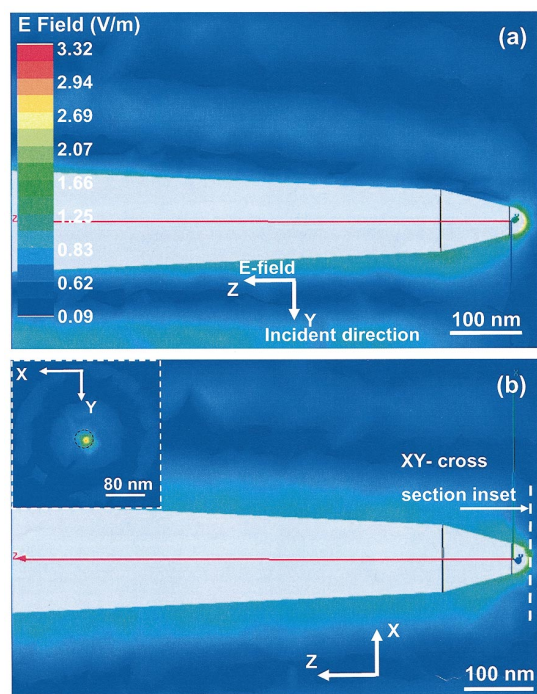

FIG. 2. (Color) Cross-sectional views of the simulated E -field distribution around the tip apex vicinity. The incident wave is along the y -axis, normal to the cone axis, with a magnitude of 1; the incident E -field is along the z -axis, parallel to the cone axis. The geometry of modeled tip is similar to what was used in the experiment. (a) ZY cross-sectional view of a tip with a curvature radius of 20 nm. The inset is the XY cross-sectional view at the plane at the tip apex. (b) ZX cross-sectional view of the same setup as (a).

was reached before laser irradiation. A KrF excimer laser (Lambda Physik Compex 205, wavelength=248 nm, pulse duration=23 ns) was used to irradiate the tip perpendicularly, with the beam size ranges from 20 to 40 mm^2 . Before each deposition, the apex of the tip was prealigned at the center of the laser beam. Compared with the size of the tip, we assumed that the laser beam was uniform at and near the tip apex. Morphological and structural characterizations were conducted by a Hitachi S-4700 field emission scanning electron microscope (FESEM) and a micro-Raman spectroscope excited by an argon ion laser at 514.5 nm, respectively. In order to examine the possibility of structural variations along the tip, Raman spectra of various positions along the tip were examined. The argon ion laser used for micro-Raman spectroscopy has a focused beam spot of 1 μm . High frequency structure simulator (HFSS v9.0, Ansoft Inc.) was used to simulate the optical field around the tip apexes.⁵

Figure 2 shows the cross-sectional views of the simulated E -field distribution around the tip apex vicinity using HFSS. The incident wave is along the Y -axis, perpendicular to the cone axis. The incident E -field is along the Z -axis, with a magnitude of 1. The geometry of the tip in the simulation is modeled similar to what was used in the experiment, with a curvature radius of 20 nm. In the YZ and XZ cross-sectional views, as shown in Figs. 2(a) and 2(b), the E -field distribution shows an optically-enhanced region surrounding the tip during the laser irradiation, with a maximum enhancement factor of 3.3 at the apex. The magnitude of the E -field decreases along the tip from the apex. The inset shown in Fig. 2(b) was an XY cross-sectional view of the plane at the tip apex, with a circularly-symmetric distribution of the E -field. The field was highly enhanced at the apex, and de-

creased radially. The field distribution shown in Fig. 2 indicates that there is a shell of optical field surrounding the tip apex with a decrease in the intensity from the apex to the tip body. Since the UV laser decomposition of organic and hydrocarbon precursors is mainly photolytic, this shell of optical field surrounding the tip apex can be used for photolytic deposition of DLC films surrounding the tip apex. As shown by Lu *et al.* that at different laser fluences there are variations in phases of the deposited DLC films,^{7,8} an examination of the phases of the deposited films along the tips will show qualitative estimation of local optical field intensity and indicate whether the near-field effects are responsible to the DLC deposition.

SEM micrographs of a W tip before and after laser irradiation are shown in Fig. 3(a). During the laser deposition, the fluence was around 1250 mJ/cm^2 . As shown in Fig. 3(a), the curvature radius of W tip before laser irradiation was around 20.4 nm, aspect ratio (tangent of half-cone angle) around 4:1. The tip was first irradiated by one pulse. There was almost no change in the morphology. (The corresponding SEM micrograph is not shown here.) In contrast to the experiment of laser deposition in a benzene solution that a single pulse of laser can generate substantial DLC coatings,⁵ LCVD deposition may require more pulses and longer irradiation since the density of carbon feedstock is much lower in a precursor vapor than in a dense liquid solution. The same tip was then irradiated with 20 pulses at a frequency of 5 Hz. A thin layer of coating was found, extending along the tip body. The curvature radius of the tip after deposition is around 25 nm. A DLC film with an average thickness of 24 nm was found covering the first 1 μm section of the tip. In Fig. 3(a), SEM micrographs also show that the coating extended to the tip body around 10–15 μm , with an average thickness around 60 nm.

FIG. 4. Raman shift of the DLC films at different locations on the W tip shown in Fig. 3(c).

Raman spectroscopy was used to characterize the structure of the films along the tip apex. The arrows shown in Fig. 3(b) are the approximate positions where Raman spectra were obtained. The circular spot at point 3 denotes the argon laser beam spot during micro-Raman characterizations, which is 1 μm in diameter. Figure 4 shows the Raman spectra of the DLC films at various positions along the tip. The spectra were Lorentzian fitted into *D*- and *G*-bands. As indicated in Fig. 4, the structure of deposited films is DLC in nature and shows variations along the tip. *D*- and *G*-bands are dominant at point 1. At points 2 and 3, the two peaks overlap and merge into a broad peak. For point 4, the Raman spectroscopy shows only noise signals. In order to examine the structural properties of the film deposited on the back of the tip, two points on the back of the tip, with position corresponding to points 1 and 2 were examined. Table I shows all the fitting parameters for spectra of DLC films along the W tip.

The Raman spectra of the DLC films are analyzed in terms of *G*- and *D*-band positions, and integrated intensity ratio of the *G*- and *D*-bands.^{10,11} As shown in the table, there are two important features that can be observed from points 1 (apex) to 4 (11 μm from the apex). First, *D*- and *G*-bands have a monotonous blue shift. Second, the intensity ratio $I(D)/I(G)$ increases as the positions being further away from the apex. It was found that increasing the percentage of four fold coordination bonds leads to a decrease in both *G*- and *D*-band frequencies instead of a mixture of the Raman peaks associated with diamond and graphite.⁹ Richter¹⁰ calculated the frequency of the *G*-band using a simple valence force model weighted by the fraction of sp^3 and sp^2 bonds. They found that the frequency shifts in the *G*-band are caused only by changes in the force constants and correspond to a certain sp^3 -bond fraction. The Raman shift of *D*-band towards lower wave number has been attributed to carbon atoms in sp^3 sites. Yoshikawa *et al.*¹¹ have reported that the ratio of the sp^2 to sp^3 bonds in amorphous carbon films increase with the intensity ratio $I(D)/I(G)$. Therefore the simultaneous blue shifts in both *G*- and *D*-bands together with an increase in the $I(D)/I(G)$ ratio suggest that the film is more diamondlike (higher sp^3/sp^2) at the apex. Along the tip apex to tip body, the films gradually become graphitic. The spectrum shows no DLC features when the position is more than 11 μm away from the apex. In addition, as shown in Table I, the

TABLE I. Fitting parameters of Raman spectra at different positions along the tip, corresponding to the arrows shown in Fig. 3(c). Note that points b1 and b2 correspond to the positions on the back of the tip which are 1.5 and 4 μm away from the apex.

Point	Distance from apex (μm)	Raman peak position		
		<i>D</i> -band (cm^{-1})	<i>G</i> -band (cm^{-1})	$I(D)/I(G)$
1	1.5	1400.7	1586	1.01
2	4	1422.6	1586.1	3.09
3	7	1485.9	1600.7	7.52
4	11
b1	1.5	1393.9	1596.6	0.87
b2	4	1416.8	1599.1	0.89

quality of DLC on the back of the tip also shows that the positions of *G*- and *D*-bands have a blue shift from points b1 to b2. The $I(D)/I(G)$ are 0.87 and 0.89, respectively. This indicates that there are substantial sp^3 species deposited on the back of the tip close to the apex. Generally, there will be no deposition on a bulk substrate if there is no direct laser irradiation. The phase-graded DLC coated on both sides of the tip at the apex suggests that there was local field surrounding the tip. This is in agreement with the simulation results and hence again confirmed that the deposition was induced by the near-field effects resulted from the interaction between the laser and the W tip.

In summary, DLC films were deposited on W tips under KrF excimer laser in a LCVD chamber. Micro-Raman spectroscopy showed a phase-graded deposition of DLC along the tips. The deposited films were more diamondlike at or near the apex. The variation in the phase of the deposited DLC films suggests a corresponding variation in the local optical intensity along the tips. This conclusion is in agreement with the simulation results suggesting that there was an optical near field gradient from tip apexes to tip bodies. Hence, local optical-near-field-induced deposition was directly confirmed.
